

CHAPTER 16.3: THE PROCESS OF SPECIATION

Natural Selection

Genetic Drift

Speciation:
the formation of new
species

Species are defined as a group of organisms
which produce fertile offspring.

Animals belonging to the same species can interbreed to produce fertile offspring

red deer hind

red deer stag

red deer fawn

fawn grows into fertile adult to mate and produce its own young

Animals that do not belong to the same species produce infertile offspring

male horse

female donkey

young mule is the offspring but is sterile (cannot breed)

New species can emerge from several circumstances:

Reproductive isolation: when two population can no longer interbreed and produce fertile offspring.

Natural selection and genetic drift continue to affect the separate species.

Behavioral isolation: when two populations are capable of interbreeding but have differences in courtship behavior or other reproductive strategies

Geographic isolation: two populations of a species are separated by geographic barriers and evolve to become separate species.

a) *Ensatina* ring species

b

Temporal isolation: two or more species evolve to reproduce at different times.

TESTING NATURAL SELECTION IN NATURE

So, was Darwin right??

These two biologists,
Peter & Mary Grant,
decided to test
Darwin's hypotheses.

[The Beak of the Finch](#)
